Abstract

Terahertz (THz) part of the electromagnetic spectrum (0.1–10 THz) holds the key for next-generation high-speed wireless communication, non-destructive biosensing, fingerprint chemical detection and imaging for astronomy and security surveillance. The limited THz response of naturally occurring materials had left a technological gap in the THz region of the electromagnetic spectrum. Artificially engineered materials termed as ‘metamaterials’, have shown great potential in THz wave interaction and its active counterpart termed as ‘metadevices’ have been widely reported for on-demand manipulation of THz waves. One of the most efficient means of realizing metadevices is to reconfigure the shape of unit cells and hence the corresponding THz response. The 50+ years of development in microelectromechanical systems (MEMS) and the wide array of microactuator designs provide a perfect platform to achieve structural reconfiguration of microscale metamaterial unit cells in both in-plane and out-of-plane directions. In this review, we present a comprehensive overview of various MEMS approaches adopted for the demonstration of THz metadevices, their advantages and limitations. The future research directions of THz MEMS metadevices are also discussed. The seamless integration of matured MEMS technology with incipient THz metamaterials provides significant advantages in terms of enhanced performances, advanced functionalities and large scale manufacturability, that is critical for the development of future THz technologies.

Keywords: MEMS, terahertz, reconfigurable metamaterials, metadevices

Nomenclature

6G Sixth generation
CESRR Complementary electrical split ring resonator
CMOS Complementary metal oxide semiconductor
DC Direct current
EIT Electromagnetically induced transparency
ESRR Electrical split ring resonator
EGaIn Eutectic gallium indium
LC Inductive-capacitive
LH Left-handed
MEMS Micro-electro-mechanical system
MIM Metal-insulator-metal
NMOS Negative-channel metal oxide semiconductor
PDMS Polydimethylsiloxane
PEN Polyethylene naphthalate
PET Polyethylene terephthalate
PPy Polypyrrole
REDOX Reduction-oxidation
RH Right-handed
SMA Shape memory alloy
SRR Split ring resonator
TE Transverse electric
THz Terahertz
TM Transverse magnetic

1. Introduction to terahertz metadevices

Terahertz (THz) region of the electromagnetic spectrum spans the frequency range of 0.1–10 THz. It is sandwiched between the electronics-dominated microwaves on the lower frequency side and the photonics-dominated infrared region on the higher frequency side. Hence, THz waves possess the combined benefits of both its neighbouring spectral regions, enabling various disruptive applications, such as high-speed wireless communication, non-destructive biological sensing, fingerprint chemical detection and imaging for astronomy and security surveillance [1–3]. However, technological development for efficient THz wave generation, detection and manipulation has remained largely limited. This is mainly due to the minimal interaction of THz waves with naturally occurring materials. Additionally, the efficient scaling up of matured microwave electronic technologies to high frequency THz or scaling down of infrared photonic technologies to low photon energy THz has been challenging. This has led to a technological gap in THz part of the electromagnetic spectrum. However, the demand for high data rate wireless communication links, highly sensitive biosensing and non-destructive imaging has accelerated the development of electronics, photonics as well as hybrid solutions for enabling THz technologies, over the past decade [4–9]. Especially, the advent of metamaterials has played a crucial role in bridging the THz technological gap. Metamaterial is an array of sub-wavelength structures, whose properties are predominantly determined by the geometry of the subwavelength structures. The subwavelength structure is also known as the ‘unit cell’ or ‘meta-atom’. The unit cells can vary widely in their shapes and sizes. Thus, metamaterials are functionally versatile, spectrally scalable, easily realizable and extremely thin and lightweight. A wide range of metamaterials have been reported for the interaction and manipulation of various aspects of THz waves, including amplitude, frequency, phase, bandwidth, polarization, absorption, chirality, resonance lineshape, and group velocity [10–21].

THz metamaterial with tunable response is termed as ‘THz metadevice’ and is a rapidly growing research field, owing to its importance from application standpoint. A plethora of THz metadevices have been reported over the past 15 years. THz metadevices can be broadly categorized into two classes, based on the active element included within the unit cell geometry to provide dynamic control—(a) inclusion of active materials, whose properties can be tuned with external stimulus and (b) structural reconfiguration of unit cell geometry using microelectromechanical systems (MEMS). The myriad of active materials with wide range of properties makes it extremely attractive for the realization of THz metadevices with varied functionalities. These active materials can be incorporated into the metamaterial as the substrate, surrounding media, part of the resonator or as an entire resonator itself. Various material systems have been explored for THz metadevices, including conventional semiconductors [22–37], phase change materials [38–41], phase transition materials [42–48], liquid crystals [49–53], 2D materials [54–65], 3D semimetals [66], topological insulators [67], perovskites [68–74], complex oxides [75–78] and superconductors [79–89]. The properties of these materials can be actively controlled with external stimuli such as electrical, optical, thermal or magnetic field. Even though, active material inclusion has been the most popular choice for realizing THz metadevices, the incorporation of additional materials brings in complication with respect to limited performance, fabrication complexity, and system level integration. Alternatively, structurally reconfigurable THz metadevices are realized through the integration of MEMS microactuators within the microscale unit cell geometry of THz metamaterials. MEMS technology has been developed for over 50 years and has widespread applications involving miniaturized, high-performance sensing and micro/nanoscale actuation [90–92]. The microscale dimension of MEMS actuators perfectly complements the micron-sized THz metamaterial unit cells. Hence, MEMS provides an ideal platform for the development of integrated THz metadevices [93]. Reviews on MEMS for reconfigurable metamaterials operating across the wide spectral range have been reported [94–98]. Alternatively, review on integration of MEMS for THz technologies including sources, detectors and functional components have also been recently reported [99, 100]. Here, we provide a comprehensive review with focus on MEMS actuator designs that have been exclusively reported for THz metadevices. Such focused review is important as the research efforts on developing metamaterial based solutions have started to gain significant research momentum, primarily propelled by THz-centric 6G communication [101], THz based viral sensing [102] and bioimaging. More specifically, MEMS metadevices will play an important role in the development of reconfigurable intelligent surfaces [103–105], holographic beam formers [35], phased array antennas [106], and lens-less THz systems [107].
2. MEMS for THz metadevices

MEMS technology has enabled a wide variety of microactuators with varied performance in terms of deformation range, reconfiguration direction, response time, power consumption, ease of integration and CMOS compatibility. Various types of microstructures can be realized with MEMS, including cantilevers, beams, diaphragms and frames. These microstructures can be mechanically deformed with external applied fields and are known as ‘microactuators’. Microactuators integrated with metamaterial unit cells enable dynamic reshaping of unit cell geometries, thereby providing tunable THz response. Various designs of microstructures adopted for THz MEMS metadevices are elaborated next. Cantilever is the simplest of microstructures that is fixed at one end and free to move at the other end. Upon applying force, maximum displacement will be achieved at the free end of the cantilever. Beams are similar to cantilevers, but are fixed at both ends. Upon applying force, maximum deformation occurs at the midpoint of the beam. Diaphragms are membrane-like structures, which are fixed on the entire perimeter and maximum deformation is observed at the centre point of the membrane. The anchors and actuation regions in these microactuators are amalgamated and hence the deformation of the microstructures are non-uniform. To achieve uniform deformation, membranes with isolated anchors are widely used. All of the aforementioned microstructures are usually adopted for out-of-plane reconfiguration of the unit cell geometry. Alternatively, frames have been adopted for in-plane reconfiguration of unit cell geometry by attaching with external actuators. Frame is a slab of material with an array of perforated holes, and are usually made of silicon (Si). The frame houses a part of the unit cells and is connected to external actuators, while the other part of the unit cell is fabricated on fixed Si structures. The in-plane movable actuators drive the frame along with a part of unit cell, relative to the fixed part of unit cell to provide dynamic THz response. Various actuation mechanisms such as thermal, electrostatics, piezoelectric, and electromagnetic can be utilized for driving the aforementioned microstructures. Among these approaches, thermal and electrostatic schemes are widely adopted, owing to their large deformation range and ease of integration. Experimental demonstrations using piezoelectric and electromagnetic approaches are yet to be reported, owing to their integration complexity. Beyond these four actuation schemes, pneumatic approach is reported for large and bi-directional reconfiguration, which is critical for specific application such as chirality switching. Furthermore, electroactive polymers which expand and contract upon applying voltage have also been reported for in-plane reconfigurable THz MEMS metadevices. Alternatively, metamaterials fabricated on flexible and stretchable substrates provide a straightforward means of achieving structural reconfiguration through mechanical bending or strain and have been reported for THz MEMS metadevices. Microfluidics integrated THz metadevices that can be filled with controlled portions of liquid metals have also been reported for THz MEMS metadevices. In this review, the reported literatures on THz MEMS metadevices are categorized based on the reconfiguration schemes. Each reconfiguration scheme is further sub-divided based on the actuator designs to highlight the advantages, limitations and functionalities enabled by specific microactuator design. The review concludes with the future prospects of THz MEMS metadevices in terms of novel explorations and potentially disruptive applications.

2.1. Thermal reconfiguration

Thermally reconfigurable microactuators are one of the popular class of MEMS actuators, which provide microscale mechanical deformation in response to change in temperature. The thermal stimulus can be provided using a furnace, heater stage or Joule’s heating by passing current. Various designs of thermal actuators for both in-plane and out-of-plane reconfiguration are available [108]. Thermal actuators provide large deformation, large stroke, continuous tunability and are relatively simpler to design and fabricate. However, thermal actuators are usually limited by their slower speed, higher power consumption, global control, sensitivity to temperature and pressure variations. Various thermally reconfigurable THz MEMS metadevices have been explored and are presented in this section.

2.1.1. Out-of-plane thermal reconfiguration.

One of the initial demonstration of THz MEMS metadevice was reported using thermally reconfigurable bimaterial cantilevers. The metamaterial unit cell comprised of gold (Au) split ring resonator (SRR) on silicon nitride (SiN) membrane as shown in figure 1(a) [109]. The silicon (Si) substrate underneath the unit cell was completely etched away, leaving the SiN membrane suspended with two cantilever anchors, attached to the substrate. The cantilevers were made of bimaterial stack of Au/SiN layers. Upon fabrication, the released SiN membranes housing the Au SRRs remained relatively flat as shown in figure 1(b). Rapid thermal annealing was used to anneal the fabricated metadevice from 350 °C to 550 °C, in steps of 50 °C. After each annealing step, the bimaterial cantilevers were permanently curved up with a larger deformation as shown in figure 1(c). The released membranes housing the SRRs were lifted from ~0° (flat) after fabrication to ~65° (almost upright position) after annealing at 550 °C. This resulted in a large change in the THz response of the metadevice after each annealing step for both EX and EY incidence of THz waves as shown in figures 1(d) and (e), respectively. Hence, by incorporating thermally driven bimaterial cantilevers with SRR unit cells, a large change in anisotropic THz response was demonstrated through reorientation of metadevice. This approach was also adopted to demonstrate spatially selective reconfiguration of unit cells by placing the bimaterial cantilevers on desired unit cells, while the other unit cells were placed on an anchorless SiN membrane that were non-deformable[110]. Upon annealing, only the unit cells suspended with bimaterial cantilevers were deformed and allowed for spatially selective reconfiguration of the THz MEMS metadevice. Hence, large and continuous deformation of unit cell
geometry with spatially-selective control was demonstrated using thermal annealing of bimaterial cantilever approach. However, this mechanical reconfiguration is caused due to the changes in residual stress in the bimaterial layers forming the cantilevers and so, the deformation of the cantilever after each annealing cycle is non-volatile and cannot be reversed. This limited the operation of these metadevices to a single cycle. The proposed approach also suffers from high power consumption and requires furnace to anneal the sample at such high temperatures.

Multicycle operation of thermally reconfigurable THz MEMS meta device was also reported using bimaterial cantilevers comprising of materials with largely different coefficient of thermal expansion [111]. Temperature driven differential expansion/contraction of the constituent material layers, results in an overall out-of-plane deformation of the bimaterial cantilever. The direction of out-of-plane deformation (i.e. upwards or downwards) with increasing temperature will be determined by the relative placement of the two materials forming the cantilever. Bimaterial cantilevers made of aluminium (Al) and aluminium oxide (Al₂O₃) stack were formed as a part of electrical SRRs (ESRR) on top of Si substrate as shown in figure 1(f). Upon fabrication, the bimaterial cantilevers were deformed upwards (away from the substrate), owing to the residual stress in the bimaterial layers as shown in figure 1(g). The measured resonance frequency of the ESRR at room temperature (300 K) was at ~0.4 THz as shown in figure 1(i). When the temperature of the metadevice was gradually decreased from room temperature to 77 K, the bimaterial cantilevers curved upwards as shown in figure 1(h). This led to a continuous blue-shift of the resonance frequency until 0.42 THz at 77 K, as shown in figure 1(i). Alternatively, when the temperature was gradually increased to 400 K, the cantilevers continuously curved downwards as shown in figure 1(h), leading to a red-shift in resonance frequency upto 0.32 THz as shown in figure 1(i). The THz resonance spectral tunability of ~0.1 THz was achieved for the overall temperature change of 323 K. Hence, a continuous, bidirectional and repeatable operation of thermally driven THz MEMS metadevice was experimentally demonstrated. Even though, multicycle operation of metadevice was demonstrated using thermal actuation, the need for external cooling and heating systems, higher power consumption and slower speed are some of the major technological challenges that needs to be addressed.

2.1.2. Electrothermal reconfiguration. Electrical current driven Joule heating of resistive elements can enable highly
compact solutions, while providing all the functional benefits of thermally reconfigurable bimaterial cantilevers. Electrically connected 2D array for bimaterial cantilevers was reported for electrothermal reconfiguration of THz resonance frequency as shown in figure 2(a) [112]. The bimaterial cantilever was made of Al and Al$_2$O$_3$ material stack and was deformed upwards upon fabrication due to residual stress. The measured resonance frequency of the as-fabricated metadevice without input current (0 mA) was at 0.85 THz as shown in figure 2(b). When electrical current was passed through the Al lines, the temperature of the entire metadevice increased due to Joule heating. This rise in temperature led to the downward deformation of cantilevers, thereby causing the resonance frequency of the metadevice to continuously red shift until 0.6 THz for 550 mA of input current as shown in figure 2(b). Similar approach was earlier adopted in a released ‘Ω’-ring enclosing a disk resonator based metadevice as shown in figure 2(c) [113].

Electrothermal actuation was also reported for active control of THz absorption [114]. Metamaterial absorbers are made of three layers—bottom reflector, dielectric spacer and top metamaterial layer. The metamaterial unit cell consisted of Au SRR on SiN plate, which was suspended by two bimaterial cantilevers made of Au/SiN with an air gap, over Au coated Si substrate which acted as the reflector, as shown in figure 2(d). The air gap between the bottom Au and top metamaterial layer formed the spacer layer. Tungsten heating resistors with thermal isolations were integrated within the unit cell to enable efficient heating of the bimaterial cantilevers. The temperature of the device was increased by passing current through the tungsten heater. With increasing temperature, the bimaterial cantilevers bent downwards, thereby reducing the air gap between the top SRR layer and bottom Au reflector. This consequently led to a reduction in absorption at $\sim$0.68 THz by 30% for the input current of 1200 mA as shown in figure 2(e). Hence, electrothermal approach is highly attractive for integrated solutions with large and continuous deformation. However, it still suffers from high power consumption, slower speed and high sensitivity to temperature and pressure variations.

2.1.3. In-plane thermal reconfiguration. Complementary to the out-of-plane reconfiguration, thermal actuators can also enable in-plane reconfiguration i.e. in the plane of the metamaterial. In-plane reconfigurable thermal actuators are made from single material layer. The popular choices of thermal unimorph actuator designs are the V-beam and U-beam actuators. The V-beam actuator also known as ‘chevron actuator’, is made of a long beam that is fixed on either side with a slight bend at the mid section, hence forming a V-shape [115]. When electrical current is passed through the V-beam, the Joule heating increases the temperature of the V-beam. This leads to the expansion of the V-beam and the mid section of the V-beam is pushed forward. Adoption of such in-plane reconfiguration for THz MEMS metadevice has been theoretically proposed [116]. The design proposed the use of metallic inclusion attached to the mid-portion of V-beam actuator integrated with SRR unit cells. By moving the metallic inclusion on the V-beam actuator, the effective capacitance of the SRR gap could be altered, thereby leading to a corresponding spectral tuning of SRR resonance frequency. Another popular unimorph thermal actuator for in-plane reconfiguration is the U-beam actuator and was also proposed for THz MEMS metadevice...
2.2. Electrostatic reconfiguration

Electrostatics is arguably the most popular choice of actuation mechanism used for the demonstration of THz MEMS metadevices. Electrostatic actuator usually consists of two electrodes—one fixed and other movable with an air gap between them. When voltage is applied across the electrodes, charges of opposite polarity accumulate at the surface of the electrodes, similar to that of a capacitor. This charge accumulation leads to an attractive force between the electrodes and pulls the suspended electrode towards the fixed electrode. Electrostatic actuators provide numerous advantages, such as ease of design, smaller footprint, potentially localized control, low power consumption and simpler fabrication. On the other hand, electrostatic actuators suffer from lower deformation range, owing to pull-in phenomenon and high actuation voltages that rapidly scale up with the air gap between the electrodes. Numerous reports on electrostatically driven THz MEMS metadevices with varied functionalities are discussed in this section.

2.2.1. Out-of-plane electrostatic reconfiguration. The simplest of the electrostatic actuator is a conductive cantilever fabricated on top of a lightly doped silicon substrate with an insulating layer in between. An array of cantilevers made of Al/Al$_2$O$_3$ bimaterial stack, fabricated on top of lightly doped Si substrate was reported to provide excellent dynamic THz performance [118]. The cantilevers were prestressed due to the residual stress between the bimaterial layers and were bent upwards after the release process, as shown in figure 3(a). This allowed for a much larger tip displacement of the released cantilevers (in $\mu$m), compared to the sacrificial silicon oxide (SiO$_2$) layer thickness of only 100 nm. It was also shown that by decreasing the thickness of Al layer, while keeping the Al$_2$O$_3$ thickness unchanged, resulted in an enhancement of initial tip displacement of the fabricated cantilevers. This consequently increased the tunable range of the resonance frequency of the cantilever-based THz MEMS metadevice. The dipole resonance of the cantilever metadevices for Al thickness of 100 nm, 300 nm and 500 nm were measured to be 0.88 THz, 0.935 THz and 0.96 THz, respectively as shown in figure 3(b). By applying voltage between the Al layer and Si substrate, the cantilevers were deformed towards the substrate, until it came in complete physical contact with the substrate. In this configuration, the ON state resonance for all three metadevices was $\sim$0.6 THz. Maximum switching contrast of 0.6 was achieved at $\sim$0.6 THz for all three metadevices as shown in figure 3(c). Hence, a simple cantilever array fabricated on lightly doped Si substrate acted as an efficient THz switch. The geometrical parameters of the cantilevers and the thickness of constituent materials could be engineered to achieve desired tunable THz response. Electrostatic actuated cantilever array was also reported for continuous spectral tunability of resonance frequency, by gradually varying the gap between the substrate and the released cantilevers [119]. In another report, simultaneous tuning of multiband resonance was demonstrated using triple cantilever resonator as a unit cell of the THz MEMS metadevice [120].

The simplicity of cantilever design and integration allows for selectively releasing a part of any resonator design and then by electrically connecting them will enable active structural reconfiguration using electrostatic actuation. Hence, the cantilever approach was reported for a wide range of reconfigurable THz functionalities. In an initial work, the side arms along with the tip arms of dual SRR unit cell were released to form ‘T’-shaped cantilevers as shown in figure 3(d), to enable electrostatically tunable magnetic response at THz frequencies [121]. Alternatively, active control of resonant electrical response was reported by releasing the ‘T’-shaped cantilever formed from the centre arms along with the capacitive tip arm of the ESRR unit cell as shown in figure 3(e) [122, 123]. Furthermore, polarization independent response was also reported for all reconfiguration states using a unique metamaterial unit cell design that consisted of eight cantilevers placed at each corner of electrically connected octagon ring, as shown in figure 3(f). The metadevice response for both $E_x$ and $E_y$ polarized THz incidence were identical at all reconfiguration states [124]. This was achieved due to the high symmetry of octagon-shaped unit cell design as well as the out-of-plane reconfiguration of cantilevers, which preserves the symmetry of unit cell in all states. Electrostatic cantilever integrated metadevice was also reported for dynamic polarization control of THz waves [125]. The unit cell design consisted of cantilever array that can be reconfigured to come in contact with an orthogonally oriented metal line as shown in figure 3(g). The metadevice response for THz incidence polarized along the cantilever length was varied strongly, while the metadevice response for orthogonal polarization remained relatively unchanged. This anisotropic response was then utilized to dynamically alter the polarization of THz waves between circular and linear states.

Furthermore, electrostatic cantilever was also integrated in a metal–insulator–metal (MIM) cavity configuration as shown in figure 3(h) for dynamic phase control [126]. The array of cantilevers formed the top metamaterial layer, while the bottom reflector was formed by a continuous Al film on Si substrate. The spacer layer was a stack of thick SiO$_2$ layer, 50 nm thin Al$_2$O$_3$ layer and a tunable air gap. Hence, by applying the voltage between the bottom Al and top cantilever, the air gap and consequently the effective spacer thickness was dynamically varied. This allowed for the switching of metadevice between over-damped and under-damped regions with corresponding phase span of full 360° and less than 180°, respectively. Such level of dynamic phase control was reported to enable THz polarization control, beam steering and holographic beam forming applications through simulation studies [127]. The MIM architecture with metamaterial as top layer was also reported for tunable THz absorption [128]. The metadevice unit cell consisted of ‘I’-shaped resonator fabricated on SiN membrane that was suspended with two cantilevers that were anchored to a fixed rectangular ring. The air gap between the top metamaterial layer and bottom reflector was reduced by applying voltage between them and this led to the gradual red-shifting of peak absorption frequency of the THz MEMS metadevice.

The fabrication process used to realize electrostatic cantilever readily allows for two isolated electrical control of the metadevice [129]. This opened a new avenue for advanced manipulation of THz waves as shown in figures 3(i)–(m). In the initial report, electrically isolated SRR and ESRR unit cells placed in an interpixelated fashion as shown in figure 3(i), was reported for independent control of magnetic and electrical resonances [130]. Then, independent reconfiguration of bright and dark mode resonators in near-field coupled metadevice was reported for amplitude modulation and spectral tuning of electromagnetically induced transparency (EIT) analogue as shown in figure 3(j) [131]. Similar approach was also employed for the realization of Fano resonance through symmetry breaking in the wave propagation direction [132]. Two SRRs with independent control formed the Fano resonator unit cell as shown in figure 3(k). By changing the height of

the cantilevers in each SRR independently, the strength of the Fano resonance was modulated. Interestingly, the presence of Si substrate broke the mirror symmetry of the metadevice in the vertical direction and enabled metahysteresis behaviour. This unique feature was used for demonstrating various logic gate operations at THz frequencies [132, 133]. In another work, complete control of anisotropic response was reported by isolating the control to orthogonally twisted cantilevers placed in a ring resonator configuration as shown in figure 3(I) [134]. Based on the combination of cantilever switched and polarization of incident THz waves, varied linear polarization response was achieved at specific THz frequency. Active switching of chirality between achiral, levorotatory, dextrorotatory and racemic states was also reported by using isolated control of orthogonally twisted ‘L’-shaped cantilevers as metadevice super cell as shown in figure 3(m) [135]. Various other functionalities were also reported using the electrically isolated electrostatic cantilever platform including switching of EIT analogue in tri-atomic metadevice [136], THz bandwidth control [137], tunable filter [138], and tunable dual band absorption [139]. The two lithography step fabrication process limits the control to only two isolated electrodes for a metadevice. However, the number of metallic layers can be scaled up and this will enable even higher level of isolation for extreme THz wave manipulation.

Even though the microcantilever on doped Si substrate enables simpler implementation of electrostatically driven THz metadevices, it suffers from additional loss due to substrate doping, limited reconfiguration range, and reduced reliability. Alternative electrostatic schemes for out-of-plane reconfiguration are also explored to address the aforementioned challenges. Electrostatically actuated microplate array, fabricated on quartz substrate was reported to perform as an efficient THz filter and modulator [140, 141]. The metadevice unit cell consisted of two SiN coated Au plates—one fixed on the quartz substrate, while the other was suspended above the fixed plate with an air gap between them (OFF-state), as shown in figure 4(a). When voltage was applied between the two Au plates, the electrostatic force pulls the suspended plate towards the fixed plate. Beyond the critical pull-in voltage, the gap between the two plates was completely closed (ON-state), as shown in figure 4(b). Thin coating of SiN dielectric on both Au plates prevents the electrical short between the two Au plates upon physical contact. The metadevice showed a large switching contrast of over 70% at 0.48 THz for an applied voltage of ~33 V, as shown in figure 4(c). The large surface area of
the plates enabled lower actuation voltage, even with a large air gap between the two plates of ~5.8 μm. Such large gaps are required to achieve high enough restoring force that would overcome the adhesion forces of the SiN coated Au plates, and bring the cantilevers back to their initial OFF state. This is important for ensuring repeatable operation of the electrostatically driven THz MEMS metadevices. Also, the use of quartz substrate alleviated the substrate related loss incurred in doped Si substrate based metadevices. In another report, Al/SiN bimaterial cantilevers were fabricated on top of the Au ESRR on semi insulating gallium arsenide (GaAs) substrate as shown in figures 4(d) and (e). Electrostatic actuation was used to electrically short the ESRR gap by pulling down the cantilever [93, 142]. This allowed for the dynamic switching of LC resonance at 0.75 THz with a contrast of over 50% as shown in figure 4(f). Integration of THz MEMS on GaAs substrate could also be used for reconfigurable THz sources and detectors. Complementary to fixed-free cantilevers, electrostatically driven fixed-fixed beams were also reported for the realization of THz MEMS metadevices [143, 144]. In this report, vertically aligned Au beam was suspended over horizontally aligned Au lines that were fabricated on SiO₂ coated Si substrate as shown in figures 4(g) and (h). When voltage was applied between the suspended Au beam and Si substrate, the vertically and horizontally aligned Au lines came in contact and were electrically shorted, thereby forming a 2D mesh pattern. This allowed for the broadband THz modulation of 70% at 30 V for a bandwidth of over 1.5 THz, as shown in figure 4(i). A variant of fixed-fixed beam, which is a membrane suspended by anchors was reported for spectrally tunable THz absorbers [145]. In all of the aforementioned approaches, the deformation range is quite limited due to the achievable thickness of sacrificial layers and the direction of actuation is always towards the substrate due to the attractive nature of electrostatic actuation. For certain applications, such as chirality switching, spiral microstructures need to be reconfigured between planar 2D spirals to 3D helices. To realize such large deformation, a novel scheme was reported by assembling a Si substrate in front of released spiral cantilevers with desired gap between them [146]. Upon applying voltage between the assembled Si substrate and suspended spiral cantilevers, the as-fabricated planar spirals were reconfigured into a 3D helices with a strong switching of chiral response, as shown in figures 4(k)–(m) respectively. All of the aforementioned works clearly highlight the key advantages of electrostatic actuation, including simpler integration, versatile design, low power operation and multichannel control to enable wide range of high-performance THz MEMS metadevices.

2.2.2. In-plane electrostatic reconfiguration. Comb drive actuator is the most popular choice of electrostatic actuators that enable large in-plane deformation [147]. Comb drive actuator consists of a pair of interdigitated overlapping fingers, in which one set of fingers is free to move, while the other set remains fixed. When voltage is applied between the two sets of fingers, the electrostatic field between the fingers drives the movable set along the in-plane direction. Electrostatic comb drive actuators can provide continuous and large displacement and hence have been extensively used for in-plane reconfigurable THz MEMS metadevices [148]. In an initial report, a pair of SRRs formed a unit cell of which one SRR was fabricated on a movable Si frame driven by electrostatic comb drive actuators, while the other SRR was fabricated on the fixed Si island, as shown in figures 5(a) and (b) [149]. The SRR housed on the frame could then be moved either towards or away from the fixed SRR, thereby forming either an opening state, closed-ring state or back-touch state configuration of the unit cell, as shown in figures 5(c)–(e), respectively. The bidirectional reconfiguration was achieved by using two comb drive actuators fixed on either sides of the movable Si frame, as shown in figure 5(a). The as-fabricated metadevice unit cell consists of two SRRs with two capacitive gaps on either sides, as shown in figure 5(b). When THz wave with TE polarization was incident at 45°, Fano-type magnetic resonance was observed at ~2.12 THz, as shown in figure 5(f). By increasing the capacitive gap from 2 μm to 6 μm between the SRRs, the resonance frequency was blue-shifted from 2.12 to 2.28 THz, respectively, as shown in figure 5(f). When the in-plane gap between the SRRs was completely closed i.e. close-ring state, no resonance was observed as shown in figure 5(g). Similarly, when back-touch configuration was formed by actuating the SRR in opposite direction, no resonance was observed as well, as shown in figure 5(h). Hence, the in-plane reconfiguration allowed for switching of magnetic resonance as well as spectral tuning of magnetic resonance frequency of the THz MEMS metadevice. The versatility of this platform allowed for the active control of various THz functionalities. Anisotropy switching was reported in a maltase cross metamaterial driven by comb-drive actuator [150]. This was realized by selectively breaking the symmetry of the cross structure along one-direction, while preserving it along the orthogonal direction in all reconfiguration states as shown in figure 5(i). In another work, the THz response of the metadevice was actively switched between polarization-dependent state and polarization-independent state by altering the lattice constant of the unit cells through in-plane reconfiguration as shown in figure 5(j) [151]. The as-fabricated metadevices had varying pitch along x-direction and y-direction and showed polarization-dependent THz response. Alternate lines of the metamaterial were fabricated on a movable frame connected to a set of comb drive actuators. By changing the relative position of the unit cells in the neighbouring lines, the lattice period was shifted to form interpixelated supercell with four fold-rotational symmetry and hence led to polarization-independent THz response. The comb drive integrated THz MEMS metadevice was also reported for polarization conversion and rotation by forming staircase structures with UP, ‘T’ and DOWN states [152]. The metamaterial consists of horizontal metallic slabs on fixed Si islands and the vertical metallic slabs were fabricated on the movable Si frame. By selectively displacing the vertical slabs, the staircase structure could be reconfigured between the UP, ‘T’ and DOWN states as shown in figure 5(k). The polarization rotation angle was reconfigured between −12.8°, 0° and +13.1° at 1.78 THz.

corresponding to UP, ‘T’ and DOWN states of the staircase unit cell. Comb drive actuators were also reported for dynamic control of broadside coupling in dual layer SRRs [153]. The metadevice consists of two arrays of SRRs stacked in a broadside-coupled manner [154]. The unit cell consists of a pair of 180° rotated SRRs separated by an out-of-plane gap as shown in figure 5(l). Due to broadside coupling, mode splitting was observed. When the relative overlap between the two SRRs was varied, a large blue-shift in symmetric mode and large red-shift in anti-symmetric mode was observed. Furthermore, strong amplitude modulation and phase shift were also achieved at specific THz frequency. Comb drive based THz MEMS metadevices have also been reported for reconfiguration of in-plane coupling in asymmetry SRRs [148]. In a more recent work, comb drive integrated substrateless metadevice was also reported for active tuning of EIT analogue [155]. Hence, comb drive actuators provide a powerful platform for in-plane reshaping of metamaterial unit cell geometry as well as lattice reconfiguration to achieve versatile THz functionalities.

2.3. Piezoelectric reconfiguration

Piezoelectric materials possess non-centrosymmetric crystalline structure that enables mechanical expansion or contraction, depending on the polarity of applied voltage. Some of the popular piezoelectric materials used for MEMS actuators include PZT, AlN, ZnO and PVDF. Piezoelectric actuators can provide continuous as well as bidirectional reconfiguration. Piezoelectric actuator housing released SRRs or in microgripper configuration for in-plane reconfigurable THz metadevices have been theoretically proposed [156, 157]. However, experimental demonstration has not yet been reported, owing to the complexity in piezoelectric MEMS device fabrication. Also the in-plane displacement enabled by piezoelectric actuation could be very minimal and might be a challenge in realizing high performance THz MEMS metadevices [156]. A more practical approach will be to use piezoelectric actuation for out-of-plane reconfiguration by adopting bimaterial cantilever configuration. The bimaterial cantilever can be made of a stack of piezoelectric and elastic layers. When voltage is applied across the piezoelectric layer, it will either expand or contract based on the polarity of the applied electric field, while the elastic layer will remain unchanged. This will lead to an overall out-of-plane deformation of the bimaterial cantilever. Such bimaterial cantilevers can be incorporated into metamaterial unit cell geometry for active control of THz response. Also, bimaterial cantilevers can also be made with oppositely polled piezoelectric layers to enable larger out-of-plane displacement for a given voltage. Piezoelectric actuation provides electrically controlled bidirectional and continuous reconfiguration, lower operational power, higher speed and can be realized using CMOS compatible processes. Currently, the exploration of piezoelectric actuation for THz metadevice is largely limited by the complexity in fabrication process, but has the potential of becoming a competitive approach for realizing efficient THz MEMS metadevices.

2.4. Electroactive polymer-based reconfiguration

Electroactive polymer based actuators have been widely used for soft robotics. π-conjugated polymer based actuator
been shown using pneumatic actuation. Pneumatics driven and bi-directional deformation of microstructures have been shown to provide significantly large, bidirectional and continuous deformation, as well as eliminates the need of metallic interconnects. This will be valuable for niche THz applications, such as chirality-based chemical sensors, THz polarizers and table-top spectrometers.

2.5. Pneumatic reconfiguration

Pneumatic actuation is realized by creating a pressure difference across substrate-free microstructures. Large, continuous and bi-directional deformation of microstructures have been shown using pneumatic actuation. Pneumatics driven THz MEMS metadevice has been reported for chirality switching [159]. The metamaterial consists of a 2D array of released planar Archimedean spiral, as shown in figure 7(b). The fabricated spiral metadevice was housed in a pressure chamber that could provide reversible pressure difference in the out-of-plane direction. When the pressure below the metadevice was increased, the 2D spirals moved upward and transformed into right-handed (RH) 3D helices, as shown in figure 7(a). For the pressure difference of 10 Pa, maximum deformation at the tip was measured to be as high as 60 µm, as shown in figure 7(c). When the pressure gradient was reversed, the planar spirals deformed downward by ~60 µm to form left-handed (LH) 3D helices, as shown in figure 7(c). Total deformation range of 120 µm was achieved using the pneumatic actuation. Such large deformation is important for strong chirality switching, as the range of spiral deformation determines the modulation of polarization state of THz wave passing through the metadevice as schematically shown in figure 7(b). A large tunable ellipticity between +28°, 0° to −20° was achieved at 1.1 THz, corresponding to the reconfiguration states of RH, planar and LH helices, as shown in figure 7(d). In another work, pneumatic actuation was reported for active tuning of resonance frequency for orthogonal linear polarizations of incident THz waves [160]. The metamaterial unit cell consisted of electrically coupled asymmetric SRRs that were placed with a sub-micron gap between them. One of the SRRs was fabricated on the fixed membrane, while the other SRR was fabricated on a microcantilever that is connected with a zigzag anchor. Upon applying air pressure across the metamaterial, the movable SRR was deformed in the out-of-plane direction by over 5 µm for 1 kPa of pressure. The corresponding spectral shift of 0.1 THz was achieved for both polarizations of incident THz. Hence, pneumatic actuation has shown to provide significantly large, bidirectional and continuous deformation, as well as eliminates the need of metallic interconnects. This will be valuable for niche THz applications, such as chirality-based chemical sensors, THz polarizers and table-top spectrometers.

2.6. Mechanical reconfiguration

Flexible substrates provide a direct means of achieving mechanical reconfigurability either by bending or stretching the substrate housing the metamaterial. Wide range of metamaterials fabricated on mechanically deformable flexible substrates were reported for active THz control [161]. Different flexible substrates, THz resonator designs and reconfiguration schemes have been reported for various functional metadevices and are discussed in this section.

2.6.1. Curvature-based reconfiguration. The primary property of any flexible substrate is the ability to bend upon applying mechanical force. Some of the popular flexible substrates used for THz metamaterials include polyimide [17, 31, 69, 73, 162–166], polydimethylsiloxane (PDMS) [167–170], polyethylene terephthalate (PET) [50, 171], parylene [172], polyethylene naphthalate (PEN) [173, 174], polypropylene [175], silicone [176] and silk [177–180]. In an initial work, metallic SRRs fabricated on PEN substrates were rolled into 3D tubes with varying diameter, as shown in figure 8(a) [173]. The resonance frequency of the planar SRR was measured at 0.75 THz, as shown in figure 8(b). When the metadevice was rolled into 3D tubes with decreasing diameter, the resonance frequency gradually blue shifted to 1.13 THz for the diameter of 4 mm, as shown in figure 8(b). In addition, the hollow core of the metamaterial was replaced with dielectric materials and the change in THz resonance frequency was used to estimate the refractive index of the core material. The high sensitivity of the metamaterial allowed
for the detection of minuscule refractive index change of $\sim 0.0075$. In another work, symmetric Au ESRR metamaterial was sandwiched between two PDMS layers and upon bending, the resonance frequency of the metadevice gradually blue shifted with increasing curvature [181]. Hence, bending of flexible substrates provides an straightforward means of achieving reconfigurability without the need for active materials, complex processing or electrical interconnections. They also enable extremely low-loss and low-cost metadevices.

### 2.6.2. Strain-based reconfiguration.

A subset of flexible substrates such as PDMS are elastic in nature and hence expand upon applying in-plane strain. This property of elastic substrates has also been used for realizing in-plane reconfigurable THz metadevices [168, 169, 182, 183]. Hexagon-shaped metallic resonators in honeycomb lattice were fabricated on a thin polyimide substrate and were then transferred to a prestrained PDMS substrate. Upon releasing the strain, the PDMS layer with metallic resonators wrinkled up, as shown in figure 8(c) [182]. Mechanical strain of 52.5% was applied to flatten the wrinkled layout as shown in figure 8(d). The relative change in THz transmission at 1.5 THz was changed continuously and a maximum change of 80% was observed between the as-fabricated wrinkled and strain-applied flat layout of the metadevice, as shown in figure 8(e). Similarly, closely spaced ‘I’-shaped resonators, fabricated on PDMS substrate was also reported for mechanically reconfigurable THz response [168]. Upon applying mechanical strain, the intercell capacitance along the length of ‘I’ direction decreased, thereby causing the resonance frequency of the metadevice to red shift. The spectral tunability of the metadevice was improved by adopting a corrugated ‘I’-shaped resonator, which provided larger intercell capacitance compared to the plain ‘I’-shaped resonators. The ‘I’-shaped metadevices were polarization sensitive. To enable polarization insensitive response, a cross resonator with corrugated capacitive gaps was reported [169, 184]. Hence, mechanically stretchable substrates provide a simpler route to achieve in-plane reconfigurable metadevices, that are essential for applications demanding non-conformal coatings, such as wearable devices and stealth technologies.

### 2.6.3. Shape memory alloy (SMA) for reconfiguration.

SMAs are phase transition materials that can be switched between two stable phases in response to applied temperature. One such SMA is nitinol (NiTi), a metal alloy composed of approximately equal atomic percentages of nickel (Ni) and titanium (Ti). NiTi shows phase transition between the martensite phase below the transition temperature and the austenite phase above the transition temperature, respectively. The phase transition temperature of NiTi is close to room temperature. NiTi also has very high DC conductivity of $\sim 1.2 \times 10^5$ S m$^{-1}$ in both the states. Hence, subwavelength-sized holes perforated in NiTi was reported as a phase transition powered THz metadevice [185]. The SMA was trained to achieve both 1D and 2D sinusoidal corrugation upon phase transition. When the applied temperature was lower than the martensite phase transition temperature, the NiTi hole array formed a 1D sinusoidal pattern as shown in figure 8(g). This resulted in polarization-dependent THz transmission response for $E_{||}$ and $E_{perp}$ incidence of THz waves with transmission amplitude of $\sim 0.45$ and 0.25, respectively, as shown in figure 8(i). When the temperature was raised above the austenite phase transition, the NiTi metadevice became flat as shown in figure 8(f). The corresponding THz response was polarization-independent for both $E_{||}$ and $E_{perp}$ incidence with maximum transmission of $\sim 0.55$ at 0.45 THz as shown in figure 8(h). Similarly, an aperture was formed in the NiTi film and was trained to have 2D sinusoidal corrugation around the aperture in the martensite phase. The THz transmission was increased to almost unity at 0.1 THz, while for the bare aperture on a flat NiTi film, the transmission was only 0.45 THz. Hence, phase transition in SMA was shown to be an efficient platform to achieve THz MEMS metadevices with memory effects and trainable properties.

### 2.7. Microfluidic reconfiguration.

Microfluidics integrated with THz metamaterials have been widely reported for sensing applications [186–190]. Interestingly, microfluidic metamaterials are also reported for THz metadevices by injecting controlled proportion of liquid metal into the microchannels [191, 192]. In an initial work, two layers of ‘S’-shaped microfluidic channels were orthogonally twisted with respect to each other and separated by 100 µm thick PDMS layer formed a microfluidic THz metadevice, as shown in figures 9(a) and (b) [193]. By filling the two channels with different refractive index materials such as mercury and air, strong optical activity was achieved at 2.56 THz. Alternatively, the polarization rotation of the metamaterial was also tuned, by injecting the top ‘S’ layer of the metamaterial with varying concentration of sodium chloride (NaCl) solution, while the bottom layer was filled with mercury. Maximum rotation angle of 16.9$^\circ$ was achieved for 0% NaCl. With increasing NaCl concentration, the polarization rotation angle gradually reduced and reached 0$^\circ$ at 16% NaCl concentration as shown in figure 9(c). In another work, eutectic gallium indium (EGaIn) was used as the liquid metal to realize THz metamaterials [194]. The shape of the injected EGaIn was mechanically stabilized by the formation of a thin oxide surface layer that allowed the fluid to maintain its configuration within the microchannel despite its high intrinsic surface energy. The EGaIn could be flowed again by increasing the intrinsic pressure to go beyond the critical value. This allowed for the reshaping of THz resonator between SRR, closed ring resonator and irregular closed ring resonator geometries as shown in figures 9(d)–(f), respectively. Each of these configurations, provided starkly different THz response. Alternatively, array of liquid metal pillars of varying heights was formed using microfluidic approach and was demonstrated to achieve polarization independent, frequency agile and wide angle THz absorption as shown in figures 9(g) and (h) [195, 196]. By increasing the liquid metal height from 30 to 90 µm, the peak absorption frequency was tuned from 0.246 to 0.415 THz, which provided a large tuning range of 51.1% as shown in figure 9(i). For a wide angle of incidence from 0$^\circ$ to 60$^\circ$,

the microfluidic metamaterial absorber showed strong THz absorption of over 90% with slight red shift in resonance frequency. The complementing features of microfluidic technology and THz metamaterials could potentially enable smart solutions by incorporating both sensing and reconfiguration modalities within a single device.

2.8. MEMS metadevice for THz detection

In all of the earlier mentioned approaches, an external stimulus drives the mechanical reconfiguration of MEMS actuators integrated with metasurface to achieve tunable THz response. Alternatively, incident THz waves can also drive the mechanical response of the MEMS actuators and hence employed for THz detection. MEMS metadevice based THz detector usually comprises of two parts—metamaterial absorber and sensing element. The metamaterial absorber is a trilayer MIM configuration, where the bottom metal layer acts as the reflector, the central dielectric acts as the spacer and top metal layer is patterned to form the metamaterial. The MIM configuration is optimized to achieve high absorption at specific frequency. Based on the top metamaterial design advanced functionalities such as polarization selectivity and multispectral absorption can be readily realized [11, 197, 198]. Hence, the absorber converts the incident THz wave to heat and a sensing element is used to measure the rise in temperature. In one of the initial works, Au SRR metamaterial based absorbers were suspended with two bimaterial cantilevers made of Au/SiNx as shown in figure 10(a) [199]. The THz MEMS metadevice showed peak absorption at ~0.7 THz and led to the heating of the suspended SRR unit cells. The rise in temperature caused the mechanical bending of the suspended SRR unit cells. A
small metallic patch was fabricated within the SRR unit cell, which was used to reflect optical readout beam incident on the SRR unit cells. Based on the mechanical deformation, the position of the reflected optical beam varied and was calibrated for the incident THz power as shown in figure 10(b). The optical reflection based readout method provides improved sensitivity of THz detection. A highly optimized design was reported using the similar approach with Al/SiO\textsubscript{2} bimaterial cantilevers suspended THz absorber [200–202]. In this case, the bottom metal layer of the absorber was also used for reflection of the optical readout beam. However, this demands for etching away of Si substrate to allow for optical readout form the backside of the device. Alternatively, Al/SiNx bimaterial cantilever suspended metamaterial absorber was fabricated on glass substrate to allow for THz sensing from the front side, while optical reflection was readout from the backside. The transparency of glass substrate to optical beams eliminates the need for etching thick substrates. A large array of 128 × 128 unit cells of MEMS metadevice was demonstrated for THz imaging application [203]. In another report, the thermomechanical deformation of parylene-C/Titanium bimaterial cantilever suspended THz absorber was measured using diffraction grating interferometer fabricated on the metal layer coated on substrate, below the suspended absorber as shown in figures 10(c)–(e) [204]. However, in the aforementioned MEMS metadevice based THz detectors, the response time is generally slow owing to the need for transfer of thermal energy and conversion to mechanical deformation. An innovative approach was reported by using a single SRR metaatom with a suspended cantilever as THz detector. The SRR metaatom
was designed to resonate at specific THz frequency and the suspended cantilever has a narrow in-plane gap of ~300 nm as shown in figures 10(f) and (g) [205]. The incident THz wave induce high-frequency currents and charges that, in turn, couple to the mechanical degrees of freedom as shown in figure 10(h). The mechanical reconfiguration of the suspended cantilevers was read out optically. This device had extremely small footprint, fast (>10 MHz) response time and potentially frequency-independent noise equivalent power. Even though thermomechanical transduction with optical readout provides higher sensitivity, it demands for complex calibration circuit to compensate the fabrication-related non-uniformity across the pixels as well as the requires precise alignment for optical readout. A more conventional approach of using bolometric detection has also been reported through integration of metamaterial absorber with MEMS bolometer as shown in figures 10(i) and (j) [206–208]. The metamaterial layer resonantly absorbs the incident THz wave and increases the temperature of the metadevice and this in turn leads to the correspondingly rise in electrical resistance of the metallic line connecting the metamaterial unit cells, determined by the temperature coefficient of resistance of the metal. The change in resistance is then read out electrically as shown in figure 10(k). The bolometer pixels are released from the substrate to ensure efficient heat transfer and enhance the sensitivity of the detector. The advanced functionalities of metamaterial combined with the high sensitivity of MEMS detectors will play an key role in the development of next-generation miniaturized and low-cost THz imagers and spectrometers [209].

3. Future outlooks

The burgeoning field of THz technologies is gaining immense research momentum, due to its potential use in 6G communications, ultrasensitive biosensing, food quality inspection and low energy imaging for security screening. Metamaterials have provided an efficient means of achieving versatile THz manipulation. The integration of metamaterial with the robust and versatile platform of MEMS will translate these demonstrations to device level solutions for potential commercialization of THz technologies. So far, the focus has been to develop THz MEMS metadevices for single functionality such as frequency tunability, modulation, polarization control, tunable absorption, chirality switching and reconfigurable delay lines. The future evolution of THz MEMS metadevices is expected to be multidirectional. Research progress made so far in the field of THz MEMS metadevices will continue to progress, focussed on improved performance and addressing the limitations of current implementations in terms of switching speed, operational power and reliability. Research direction on exploring novel reconfiguration schemes, such as piezoelectric actuation, phase transition powered THz metadevices will also be a major thrust in the near future. Simultaneously, system level demonstration of THz metadevices by integrating control circuits and MEMS packaging will become essential for translation to commercial production [210]. Our perspective on some of the future research developments in the field of THz MEMS metadevices are discussed in this session.

3.1. Phase-transition powered reconfiguration

Large out-of-plane deformation to form reconfigurable 3D microstructures for THz MEMS metadevices have been reported either through annealing or pneumatic actuation [109, 159]. Both of these approaches require bulky systems for reconfiguration and are not attractive for commercial solutions. Alternatively, electrically reconfigurable out-of-plane deformation in THz MEMS metadevices are limited to small out-of-plane deformation [112, 118]. Recently, phase transition materials such as vanadium dioxide (VO2) have been reported to achieve huge deformation with displacement to length ratio of ~1, as shown in figure 11(a) [211–214]. Interestingly, the phase transition can be triggered using electrothermal stimulus and could enable highly integrated solution for realizing dynamic switching of metamaterial between planar and 3D configuration. Such large reconfiguration is essential for various applications, including chirality switching, widely tunable filters and absorbers. The range of deformation and transition temperature could also be varied either by doping or strain engineering of VO2 [215]. Additionally, the memory effect in VO2 can also be exploited for realizing THz memory metadevice with well-defined multilevel states, compared to the earlier reports [42]. Furthermore, the large strain built in the VO2 layer will also ensure higher reliability of MEMS switches as it prevents stiction, which is one of the most common failure mechanism in electrostatic cantilever devices [216]. The availability of wide range of phase transition materials with unique properties could potentially enable novel functionalities in THz MEMS metadevices [214]. Currently, the experimental demonstration of VO2 based THz MEMS metadevice is lacking, majorly due to the complexity in the fabrication, requiring large area devices. However, this challenge can be readily addressed and whole new sub-field of phase-transition powered THz MEMS metadevices can entail.

3.2. Three-dimensional reconfiguration

The wide variety of MEMS actuators with unique features can be co-designed and integrated with THz metamaterial to enable reconfiguration in all three spatial dimensions. An envisioned 3D reconfigurable metamaterial design is schematically shown in figure 11(b). It consists of two sets of comb-drive actuators for 2D planar reconfiguration, while the cantilevers integrated on the movable frame can enable out-of-plane reconfiguration. Hence, generic metamaterials can be fabricated and can be reconfigured based on the specific needs of various applications. This will be instrumental in driving down the cost of manufacturing, thereby making it an attractive solution for a wide range of THz applications.

3.3. Programmable reconfiguration

Programmable metamaterial is a device in which each unit cell can be addressed individually. This enables a single metadevice to be programmed to achieve various functionalities such as beam steering, holographic beam forming, and spatial light modulation [217]. Hence, programmable metamaterials
are also known as software controlled metamaterials or reconfigurable intelligent surfaces. Programmable THz metamaterials are critical for the realization of holographic beam forming, dynamic beam steering and information metasurfaces in 6G communication links [104]. However, currently MEMS approach is limited to dual control, at best. Alternate solutions for higher level of control in active materials based THz metadevices, have been reported using VO$_2$ [45], liquid crystals [51, 53], high electron mobility transistor [29, 33, 218, 219], graphene [59, 220] and photoconductive semiconductor [221, 222]. These approaches are limited to line-wise or sub-array level control with compromised performance either in terms of phase contrast, speed or power consumption. Recently, NMOS transistor integrated THz programmable metasurface was reported for high speed and multifunctional operations [35]. However, the inherent limitation of operational frequency of NMOS transistor shows low switching contrast at 0.3 THz and hinders its scalability to even higher frequencies in the future. MEMS technology can provide an efficient solution with significantly larger switching contrast and lower power consumption. Simulation studies as shown in figure 11(c) validates the potential use of MEMS for the realization of THz programmable metamaterials [127]. However, the complexity in fabrication, integration and characterization has hindered its experimental demonstration. Experimental realization of MEMS programmable THz metasurface will be an important research direction, owing to its relevance in 6G communications and integrated sensing applications [6, 35, 107].

3.4. Multidomain reconfiguration

Multidomain reconfiguration is critical for the realization of metamaterials with multiple functionalities and is gaining significant research attention, recently [39, 47, 183, 217]. Integration of MEMS with alternate approaches to alleviate the limitation of either of the approaches will be a major research direction in the future. Recently, the long-standing issue of narrowband operation of metamaterial integrated ultrafast THz modulators was addressed by integrating MEMS cantilever on ion-irradiated Si substrate as shown in figure 11(d) [112]. The electrothermal actuation of cantilevers enabled the operational frequency to be continuously tuned over the large spectral range of 0.3 THz, while the ion-irradiation of Si substrate enabled ultrafast modulation of THz resonance in picosecond timescales. Such integration of complementing

technologies will become more attractive as they enable multifunctional feature within a single device.

4. Conclusions

The nascent field of THz metamaterials is rapidly growing due to its huge potential in various disruptive applications including - 6G wireless communications, non-destructive biosensing and imaging for security screening. The demand for technological translation of THz metamaterial into commercial solutions is becoming more crucial. The matured field of MEMS technology with its wide array of actuator designs and enhanced performance provides the perfect reconfiguration platform for large scale, miniaturized, low cost realization of THz devices. The wide range of MEMS actuators and their performance specifications are summarized in table 1. The variety of MEMS actuator designs and potential integration with complementing technologies for advanced metamaterial reconfiguration will play an important role in realizing multifunctional and programmable THz metadevices in the near future.
